Abstract. The flux density from undetected sources in the observing beam of a telescope produces source confusion noise in the resulting maps of the sky, and thus limits sensitivity. In a recent paper [1] we discussed this effect in the millimetre/submillimetre (mm/submm) waveband, using a simple model of galaxy evolution that could account for the gravitationally lensed images of distant dusty galaxies newly discovered in the fields of clusters of galaxies [3]. New models explain all the available mm, submm and far-infrared data [2]. The associated predictions of source confusion noise are presented here. The new and old estimates agree to within a factor of two on angular scales between about 0.3 and 50 arcmin, and are most similar on angular scales of about 1 arcmin. The new estimates are greater/less than the old ones on larger/smaller angular scales.

Source confusion noise is a significant concern for both galaxy surveys and cosmic microwave background radiation (CMBR) anisotropy measurements in the mm/submm waveband. The dominant source of confusion noise is expected to be distant dusty star-forming galaxies and active galactic nuclei (AGN). The population of these objects was determined for the first time last year [3], and used to make the first estimates of mm/submm-wave confusion noise [1] based on direct observations.

By modeling the results of the observations in more detail, and taking into account the recently measured spectrum of extragalactic background radiation in the mm, submm and far-infrared wavebands, the form of evolution of distant dusty galaxies has now been determined more accurately. Families of galaxy evolution models that are consistent with all the observations are described elsewhere [2]. These new results allow us to derive more definitive estimates of source confusion noise, and to determine the model-dependent uncertainties in the estimates: see Fig. 1. More details and references to the range of ground-based and space-borne telescopes and instruments included in Fig. 1 can be found in [1].

At longer wavelengths in the mm waveband the contribution of non-thermal radio sources to the population of confusing sources is expected to dominate that of dusty galaxies and AGN. The importance of confusing radio sources at frequencies from about 10 to 100 GHz is rather uncertain at present, but is under active investigation because of its significance for CMBR anisotropy measurements.

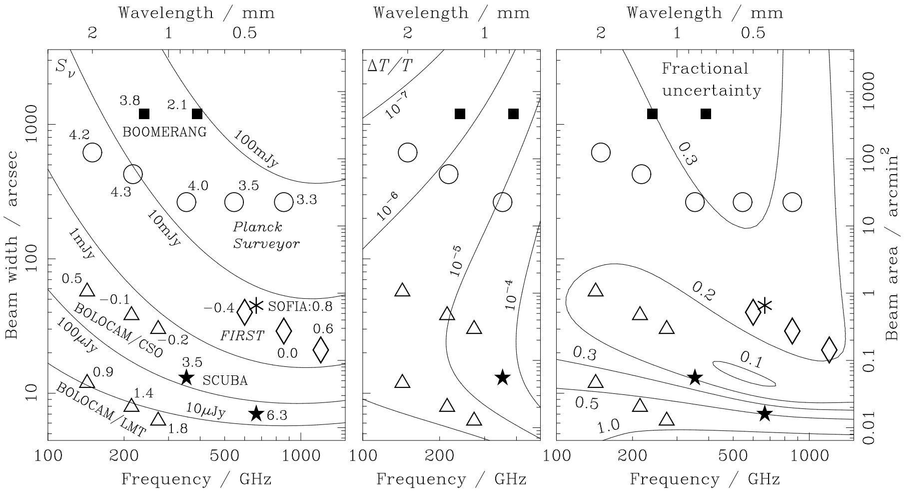

Figure 1: 1σ confusion noise as a function of both observing frequency and angular scale, presented in units of noise equivalent flux density S_ν (left) and relative CMBR temperature uncertainty $\Delta T/T$ (centre). The estimated model-dependent uncertainty in the results is shown on the right. The resolution limits and observing frequencies of several telescopes are also plotted using different point styles. The two-digit numbers alongside the points represent the logarithms of the integration times in hours after which confusion noise is expected to exceed instrumental noise for each telescope; for comparison, 1 day, 30 days and 1 year correspond to values of 1.38, 2.86 and 3.94 respectively. These times refer to a single-pointed imaging observation, except for *Planck Surveyor*, for which the times refer to the noise per pixel expected in a 14-month all-sky survey. The resolution limit of a large interferometer array, such as the MMA, would lie below the bottom of the panels. The corresponding two-digit numbers for the MMA are -0.1 at 353 GHz and 4.1 at 230 GHz, assuming a 3-arcsec beam. For details of the instruments see [1].

This paper provides the latest estimates of source confusion noise due to distant dusty galaxies and AGN in the mm, submm and far-infrared wavebands. The accuracy of the predictions as a function of the angular resolution and frequency of observations is assessed for the first time.
